

# Descending into ML: Training and Loss

**Estimated Time:** 6 minutes

**Training** a model simply means learning (determining) good values for all the weights and the bias from labeled examples. In supervised learning, a machine learning algorithm builds a model by examining many examples and attempting to find a model that minimizes loss; this process is called **empirical risk minimization**.

Loss is the penalty for a bad prediction. That is, **loss** is a number indicating how bad the model's prediction was on a single example. If the model's prediction is perfect, the loss is zero; otherwise, the loss is greater. The goal of training a model is to find a set of weights and biases that have *low* loss, on average, across all examples. For example, Figure 3 shows a high loss model on the left and a low loss model on the right. Note the following about the figure:

- The red arrow represents loss.
- The blue line represents predictions.

**Figure 3. High loss in the left model; low loss in the right model.**

Notice that the red arrows in the left plot are much longer than their counterparts in the right plot. Clearly, the blue line in the right plot is a much better predictive model than the blue line in the left plot.

You might be wondering whether you could create a mathematical function—a loss function—that would aggregate the individual losses in a meaningful fashion.

## Squared loss: a popular loss function

The linear regression models we'll examine here use a loss function called **squared loss** (also known as **L<sub>2</sub> loss**). The squared loss for a single example is as follows:

```
= the square of the difference between the label and the prediction  
= (observation - prediction(x))2  
= (y - y')2
```

**Mean square error (MSE)** is the average squared loss per example over the whole dataset. To calculate MSE, sum up all the squared losses for individual examples and then divide by the number of examples:

$$MSE = \frac{1}{N} \sum_{(x,y) \in D} (y - \text{prediction}(x))^2$$

where:

- **(*x*, *y*)** is an example in which
  - ***x*** is the set of features (for example, chirps/minute, age, gender) that the model uses to make predictions.
  - ***y*** is the example's label (for example, temperature).
- **prediction(*x*)** is a function of the weights and bias in combination with the set of features ***x***.
- ***D*** is a data set containing many labeled examples, which are **(*x*, *y*)** pairs.
- ***N*** is the number of examples in ***D***.

Although MSE is commonly-used in machine learning, it is neither the only practical loss function nor the best loss function for all circumstances.
